

A Time-Optimal Self-Stabilizing Synchronizer Using a Phase Clock

Baruch Awerbuch, Shay Kutten, Yishay Mansour, Boaz Patt-Shamir, and George Varghese

Abstract—A synchronizer with a phase counter (sometimes called asynchronous phase clock) is an asynchronous distributed algorithm, where each node maintains a local “pulse counter” that simulates the global clock in a synchronous network. In this paper, we present a time-optimal self-stabilizing scheme for such a synchronizer, assuming unbounded counters. We give a simple rule by which each node can compute its pulse number as a function of its neighbors’ pulse numbers. We also show that some of the popular correction functions for phase clock synchronization are not self-stabilizing in asynchronous networks. Using our rule, the counters stabilize in time bounded by the diameter of the network, without invoking global operations. We argue that the use of unbounded counters can be justified by the availability of memory for counters that are large enough to be practically unbounded and by the existence of reset protocols that can be used to restart the counters in some rare cases where faults will make this necessary.

1 INTRODUCTION

A synchronizer [4] is a distributed algorithm that enables algorithms designed for synchronous networks to execute correctly on asynchronous networks. It simulates the “lock-step” property of synchronous networks. That is, in synchronous networks, the computation is performed in rounds, each performed exactly at the same time at all the nodes. The duration of a round is enough for a node v to receive messages from all the neighbors (or to read all the neighbors), to compute everything that v needs to compute based on these values (and based on v ’s own state), and to send messages with the results to all the neighbors (those messages can be read by the neighbors in the next round). Let pulse i at node v be the event that starts the i th round of the execution in node v . When no confusion arises, we use the names round and pulse interchangeably.

A synchronizer is an algorithm that generates a series of events called pulses in every node in asynchronous networks. Pulse $i + 1$ is generated in a node v after all the messages sent to node v in pulse i have arrived. That is, the i th pulse at node v can be used by an application at node v to know that

the application can now compute the same results that it could have computed in a synchronous network after round i ended. Note that this does not necessarily mean that v uses a pulse counter, and even if v does, the value $i + 1$ is not necessarily exposed to v ’s neighbors. Indeed, the synchronizer of [4] uses a counter modulo 3.

A phase clock [30], [43], [26], [31], [28] in a synchronous network is a distributed algorithm that maintains in every node a copy of an integer valued variable, the counter, or the clock, which is incremented at every pulse. The values of all the copies are supposed to be always the same (in the literature, such clocks are said to move in unison [26], [31], [28]). As noted, for example, in [30], this task is not trivial, even when given that the network is synchronous.

In this note, we present a synchronizer that also supplies a phase clock for the resulting synchronous network. In fact, we do not address these two tasks separately. The implementation of the phase clock (in the asynchronous network) is our method for implementing the synchronizer. That is, in our synchronizer, every node does keep the pulse number in a counter (clock) that is shared with its neighbors (this can be implemented in a message passing system by sending this value to the neighbors from time to time). Here, this value serves two purposes. First, when the clock value at node v is $i + 1$, an application at node v can know that messages of round i sent to v by v ’s neighbors already arrived. Second, v ’s neighbors can know that v is done sending messages for round i and is now sending messages of round $i + 1$.

When the algorithm is applied to an asynchronous network, the clock values at a node v may still be larger by 1 than the value at its neighbor u . Still, a synchronous algorithm can be applied to the network, since in this case, v waits (before taking any step intended for the next time unit) until u ’s value is incremented.

As noted, for example, in [30], in a synchronous network, if the clocks have the same value, then no communication is needed, since they are incremented at the same rate. Actions of the algorithms are then needed only to 1) detect that the clocks are “out of phase” and 2) bring the clocks

back to the correct situation, where they are equal. In asynchronous networks, the algorithm needs communication also in order to increment the clock, even when the clocks are “in phase.”

Our algorithm has the important feature that it starts operating correctly, *regardless of its initial state*. That is, it is *self-stabilizing* [19]. In practice, this means that the algorithm adjusts itself automatically to any change in the network or any unpredictable fault of its components, so long as the faults stop for some sufficiently long period. For example, assume that two partitions of a network merge (or two peer-to-peer networks merge), and the clock values in each partition are very different than those in the other. The algorithm will bring them to a correct global state, where no values gap exists.

The algorithm stabilizes in time proportional to the diameter of the network, which is optimal. As detailed below, this improves both the time complexity of previous algorithms and the time complexity of algorithms that were published after the original version of this paper.

Problem statement. We are given an asynchronous message passing network, and our objective is to implement a *distributed pulse service* at the nodes. The service must provide the node at all times with a *pulse number*, subject to the following conditions:

Synchronization. Any message sent at local pulse i is received at the other end point before local pulse $i + 1$ (of the other end point).

Progress. There exist parameters Δ and ρ (that may depend on the network topology) such that for any time interval of length $t > \Delta$, the number of consecutive pulses generated at every node is at least $\rho \cdot (t - \Delta)$. The parameter Δ is called *network slack*, and ρ is the *progress rate*.

A self-stabilizing protocol is required to satisfy these conditions only after a certain *stabilization time* has elapsed. Additional intuition and an elaborate description of the desired properties from such a service are given in Section 3.

The concept of unbounded counters. By the definitions used in this paper, the value of the clock is supposed to grow unboundedly. As detailed below, under *related work*, effort was invested in the literature in the nontrivial task of bounding the clock value. Hence, in terms of the assumption on the memory, the result in this paper is weaker than in some other papers that we reference. On the other hand, the result in the current paper is stronger in terms of the time complexity. Having said that, let us try motivating the theoretical assumption of “unbounded counters.”

First, let us note that the theory of computer science often assumes memory unbounded machines. For example, a Turing machine is assumed to have an infinite tape. A machine with only a finite tape would be a finite state automaton, which is usually considered too weak a model to represent a realistic computer. An informal motivation may be that a real machine (as opposed to a Turing machine) may not possess infinite memory, but it has “enough” memory for the specific instances of the problems that it encounters. Another informal assumption mentioned sometimes is that if a machine exhausts its memory, then it will be given additional memory either by having people upgrade it or by accessing some remote reserves.

Similarly, it is not difficult to use a clock variable that is “virtually” unbounded. For example, if the clock has

several hundreds of bits, then the clock value will not reach the bound, unless a fault tampers with the value and sets it very high. Hence, had we not required self-stabilization, an unbounded clock would not have posed any problem whatsoever (except in the sense of a constant factor in the memory complexity; recall that in this paper, we address the time complexity).

A self-stabilizing algorithm must assume that a fault may occur. Here, our assumption of an unbounded clock prevents such a fault from bringing the clock close to a bound. We note that unbounded memory, even for fault-tolerant systems and unbounded clocks, are often assumed in the literature (for example, see [27], [31], [32], [2]). In addition, papers that use memory that is $O(\log n)$ when n , which is the number of nodes, is not known and may change may also be viewed as using unbounded memory.

We would nevertheless like to mention that there exists a tool in the literature that can be used to solve the case that a clock that is supposed to be “practically unbounded” does reach a bound. This is not necessarily an efficient mechanism. However, if the size of the clock is so large that it is “practically unbounded,” then this happens rarely, so efficiency may be somewhat less important.

Such a mechanism is a self-stabilizing *reset* protocol. Note that reset is beyond the scope of the current paper (that deals with unbounded counters) and is mentioned here only as a motivation. However, protocols were suggested in the literature, for example, see [3], [9], [7], [45], [51], [23], [50], [13], [21], [5] to name just a few. Moreover, it was noted in [1] that it is rather easy to translate a self-stabilizing spanning tree construction protocol into a reset protocol. As mentioned below, the important work of Spinelli and Gallager [48] can also be transformed into a reset protocol if we ignore the complexity.

A general approach to bounding unbounded counters by using reset appeared in [8] (please see references therein for papers presenting algorithms using unbounded counters). Let us just sketch here the idea in that paper. A reset protocol can be triggered by any nonempty subset of the nodes. It is supposed to bring the network into a target state, which is some predefined (legal) initial state. In the case of an asynchronous system, a protocol (including a reset protocol) cannot “act at the same time” in different nodes. Hence, the actual target state is one that is a legal successor of the above initial state. Moreover, the actual target state is “close” to the desired initial state in the sense that an asynchronous algorithm cannot distinguish between them. More formally, both the actual target state and the intended one can have the same snapshot. Hence, if the clock value at some node (or nodes) reaches the bound, then the reset protocol resets the values at all the nodes to an intended target initial state of zero value (actually, the system is reset to an actual target state, where some of the values already moved up from zero but are not “too far,” say, polynomial in n).

Now, having established that “unbounded” clocks can be used in practice (and even that they can be bounded if so desired), let us try to discuss where their use can be more desirable. First, note that, at least, in synchronous networks, there exists a trivial solution that minimizes the number of

clock states. That is, the pulse assumed in the synchronous networks model is already a clock whose number of states is 1. This is good enough for some applications. For other applications, the phase clock problem in a *synchronous* network can be viewed actually as “how the number of clock states can be *increased*” (the observation that the case of a higher number of clock values may be harder than the case of a smaller number is also implied in [36]).

In general, application requirements may sometimes call for a clock that is unbounded. Applications written for a model where a clock is assumed may include a statement such as “wait x time (increments of the clock value) and then take an action,” where x depends on the specific instance of the input. It may even be the case that x is computed by the application at runtime and that no a priori bound on x is known in advance. Looking at an application program and finding out before an execution what the value of x may even be undecidable. A clock of some constant number of states may not be able to supply this service for such an x .

Of course, an application may be able to use a constant number of state clock to implement its own, say, x states clock. However, this implementation requires solving a version of the phase clock problem: Given a clock with a states, design a clock with a given of $b > a$ states.

Finally, the designers of a clock with a bounded number of steps are more likely to take an action that decreases the value of the clock (for example, to zero out its value). Such an action is indeed taken in algorithms presented in some of the papers mentioned below. We expect a typical application using a phase clock to expect the value of the clock to be monotonically increasing. Such an application may face problems with decreases in the value of the clock.

Previous and subsequent work. The problem discussed here bears some resemblance to the problem of clock synchronization as addressed, for example, by the Internet Time Protocol [42]. As mentioned in [11], there are differences between the two problems. Because of the very rich literature on the latter problem, we cannot survey it here.

Synchronizers were the target of considerable research, for example, [4], [12], [47], [10], [6]. The concept of self-stabilization was introduced by Dijkstra [19]. A few general “stabilizer” schemes that upgrade nonstabilizing protocols to be self-stabilizing have been proposed. The problem (termed there *unison*) of maintaining clocks in phase in synchronous networks was discussed in [26] for unbounded clocks. The algorithm was not self-stabilizing.

In [31], two self-stabilizing unbounded phase clock algorithms for *synchronous* networks were suggested. We note that it is easy to see that one of these algorithms (an adaptation of the algorithm in [26]) stabilizes also in asynchronous networks. However, its stabilization time is a function of the initial difference between the clock values. This difference is controlled by faults and, hence, it may be arbitrarily large. The second algorithm presented in [31] uses a rule that, as shown in the current paper, does not stabilize in asynchronous networks.

Several papers were devoted to bounding the size (in bits or in states) of the clock. Two stabilizing bounded values clock protocols for *synchronous* networks are presented in

[30]. The first was intended only for tree networks. Its stabilization time is the diameter of the network. The second is a probabilistic protocol for general (synchronous) networks. A specific setting is given in [30], where the *expected* stabilization time is exponential.

Other papers dealing with special topologies were suggested, for example, [39], [33], [34]. In [11], a bounded value self-stabilizing algorithm for *synchronous* networks is presented. The problem there is named *digital clocks*, and applications to chip designing are explained. The rule used there is shown here not to stabilize for asynchronous networks. In [17], the assumptions are both that the network is synchronous and that a node can read in an atomic step the values of all its neighbors. The algorithm uses a rule that we show not to stabilize in asynchronous networks (the main contribution in [17] is the reduction in the size of the clock).

All of the above papers deal with the synchronous case. In [28], a bounded-value self-stabilizing algorithm for *asynchronous networks* is given. The stabilization time there too is a function of the initial difference between the clock values. Recall that this could be arbitrarily large. We note that the advantage of our algorithm compared to that of [28] is manifested in the case that no rollover is necessary (we assume unbounded counters) or if rollover (reset) events are rare, as in the case when a clock has hundreds of bits. In other cases such as a deeply embedded very low power network, relatively lean clocks with few bits are quite useful because clock values can be piggybacked on messages with minimal cost. In these cases, rollover might be relatively frequent, and it can be handled gracefully by the algorithm in [28].

Two papers that appeared after the original version of this paper deal with bounded counters, *asynchronous* networks, and self-stabilizing protocols. They improved the time of other papers mentioned above; however, this improvement relies on the assumption that certain graph properties are known. In [29], it is assumed that a bound on the diameter of the network is known, and the stabilization time depends on this bound. In contrast, for our algorithm, the time is of the order of magnitude of the *actual* diameter (the main contribution of [29] is the useful additional property of time adaptivity; that is, the stabilization time is proportional to the number of faults). Recently, in [16], it is assumed that the algorithm has access to a known bound on the size of cycles with certain properties (such as the largest hole in the graph). The stabilization time depends on that bound (the main contributions of [16] are the bound on the size of the counter and the demonstration that phase clocks are applicable to a wide range of applications). In [16], in every case that a node notices that its clock value is not consistent with that of a neighbor, the node, in effect, resets the whole system. We try avoiding such a drastic measure. For example, if a new node joins the network, with its clock value being 0, then the clock is corrected in $O(1)$ time without a reset.

Some of the clock papers deal with additional issues. For example, a node in some of the algorithms performs a step based on looking at one neighbor at a time (in our algorithm, a node first reads all the neighbors; however, we do not assume that this is done atomically). Other

papers combine dealing with transient state faults (by self-stabilization) and dealing with other kinds of faults [24], [25], [20], [46], [44]. The above survey is by no means complete. We mainly mention here papers that we also mention in the next section. There, we demonstrate why the logic used by some of these papers does not yield optimal stabilization time or, sometimes, even stabilization at all in the asynchronous model.

A somewhat different problem was studied in [35], [36], [37]. There, all the clocks should reach phase i before phase $i + 1$ is started (the implementation of a synchronizer, studied in the current paper, only requires that the difference between the clocks of neighbors is at most 1, and this allows for large differences between clocks of nodes that are far away). In [35], a known upper bound on the diameter is assumed, and the stabilization time there depends on that upper bound rather than on the actual diameter. In [36], [37], the stabilization time depends on the number of different clock values in the faulty state. In the worst case, this number can be $\Omega(n)$ (where n is the number of the nodes), which is much larger than the actual diameter that is a constant in the system studied in [36] (the main issue in [36], [37] is tolerating multiple types of faults).

In the discussion of unbounded counters above, we mentioned references for self-stabilizing reset. It is worth stressing the important work of Spinelli and Gallager [48] on topological update in dynamic networks. This algorithm has many attractive features (in addition to its simplicity). The main property of the algorithm is that it stabilizes in time proportional to the diameter. Given such a self-stabilizing protocol, many tasks become much simpler, including the task of constructing a reset protocol. The space and communication complexity of this algorithm is high.

Our results. We present a simple new rule for the self-stabilizing synchronization of networks, with network slack *diameter* and progress rate 1. Our rule does not invoke global operations, stabilizes in time linear in the actual diameter of the network without any prior knowledge, and does not require any additional memory space (other than for the pulse counter itself). By the lower bound in [39], this stabilization time is optimal. In the course of developing this rule, we obtain some interesting results regarding common synchronization rules, with applications to clock synchronization schemes. In particular, we show that rules used in other contexts (especially rules used in algorithms for synchronous networks) do not yield correct results here. We believe that the analysis of the new rule captures some of the inherent properties of synchronization.

Paper organization. This paper is organized as follows: In Section 2, we define the basic notations and the model of computation that we use. In Section 3, we develop the requirements from a desirable synchronization scheme by exploring the disadvantages of some popular schemes. In Section 4, we specify the new synchronization rule and analyze its complexity. In Section 5, applications to problems other than synchronizers are mentioned.

2 NOTATIONS AND MODEL OF COMPUTATION

We model the processor network as a fixed undirected graph $G = (V, E)$. For $u, v \in V$, we denote by $dist(u, v)$ the

length of the shortest path between u and v . We follow the notational convention that $n = |V|$ and that

$$d = \text{diameter} = \text{diameter}(G) = \max_{u, v \in V} \{dist(u, v)\}.$$

For each node $v \in V$, we denote $\mathcal{N}(v) = \{u : dist(u, v) \leq 1\}$.

We assume the model of *unit capacity data links*, in which there is at most one outstanding message in transit on every channel at any given time. If an outgoing link is not empty, then the sender cannot send anything to it until the link becomes empty (in [7], [50], it was justified as a realistic model for any message passing system, with *some* bound on the capacity of the channels).

The message delivery time can be arbitrary. For the purpose of analysis, we normalize time so that each message is delivered in at most one time unit. That is, given an execution (for example, see [41]) of a distributed algorithm, assign any duration to the delivery time of each message, as long as this assignment is consistent with the execution (and the relation *happened before* [38]). Call the longest such duration *one time unit*. The time complexity is the worst case (over the above duration assignments) number of time units of an execution. We note that computing the time according to this assumption is equivalent to computing it according to another common method of *asynchronous rounds*. See definition for time, for example, in [41], [49].

Note, that by the time a message arrives at its destination, the state at the sender may have already changed. In terms of the notion of the scheduler assumed sometimes in the context self-stabilizing systems, this is equivalent to a *distributed daemon* [15]. Without loss of generality, it is nevertheless common to assume in a distributed asynchronous system that an event (of receiving a message, computing, and possibly sending messages) at a node is atomic. Note that this does not restrict the model, since even if several nodes take an action exactly at the same time, the result of the actions of each node v cannot be known to other nodes until v 's messages reach them.

We use the method of *local detection* or *local checking* [1], [7], [50], in which each node constantly sends its state to all its neighbors. This enables us to present our protocol in a compact formulation of local *rules*. These rules are functions that take the state of the neighborhood (made available by the underlying local detection mechanism) and output a new state for the node.

3 REQUIREMENTS AND EXAMPLES

In this section, we consider a few preliminary ideas for synchronization rules. These ideas are not arbitrary. In addition to their being intuitive, these ideas were used in previous work, as well as in papers that appeared after the original version of this paper. In other contexts (mainly in the context of synchronous networks), these ideas were shown to yield correct algorithms, whereas in our context, they fail (or, at least, are not time optimal). By studying the properties of these algorithms, we develop and demonstrate the requirements from a desirable scheme.

We start with a definition of the basic requirement of synchronization.

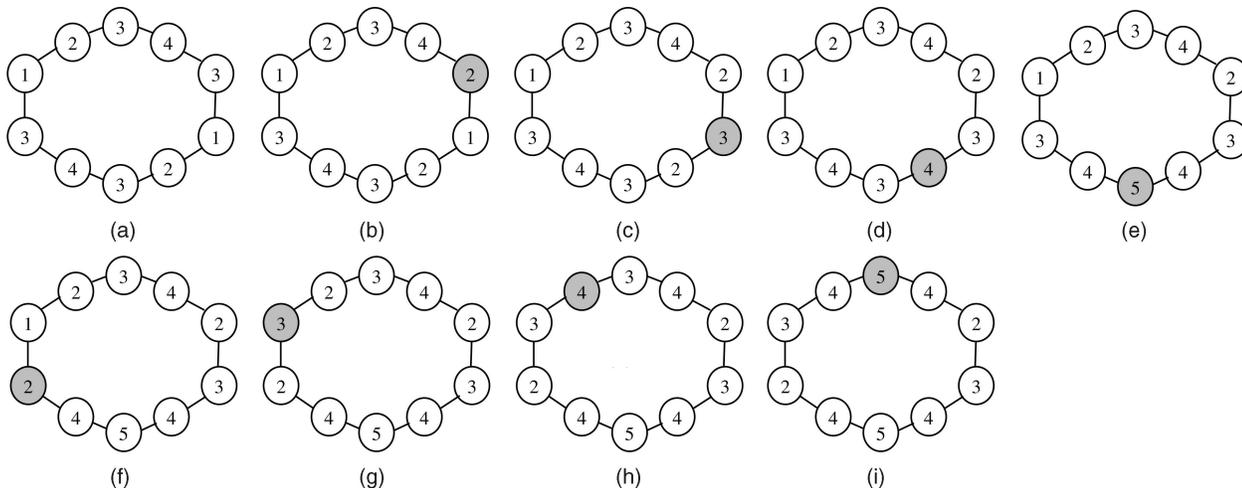

Fig. 1. An execution using Rule 1. The node that moved in each step is marked.

Definition 3.1. Let $G = (V, E)$ be a graph and $P : V \rightarrow \mathbb{N}$ be a pulse assignment (where \mathbb{N} is the set of natural numbers). We say that the configuration (G, P) is **legal for link** (u, v) , denoted $\text{legal}(u, v)$, if $|P(u) - P(v)| \leq 1$. The configuration is said to be **legal for a node** v if it is legal for all its incident links. The configuration is said to be **legal** if it is legal for all $e \in E$.

The idea behind Definition 3.1 is explained as follows: In the synchronous setting, all messages sent at pulse i are received by pulse $i + 1$. When we simulate executions of synchronous protocols on an asynchronous network, we do not have a global pulse-producing clock. Rather, we want to maintain the *validity* of the messages sent. This can be done by ensuring that a node sends pulse $i + 1$ messages only after it has *received* all the pulse i messages from its neighbors. Since message delivery is not simultaneous, there can be a skew of the pulse counters at neighbors, but this skew is allowed to be at most 1: if the pulse numbers at two adjacent nodes differ by more than 1, then necessarily, the node with the higher pulse number has advanced without receiving all messages of prior pulses. This notion of legal configuration gives rise to the following simple synchronization rule, which is implicit in the α synchronizer in [4] (we note that self-stabilization is not a concern in [4]; however, similar rules are used in papers that did ensure self-stabilization [11], [31], [30], [17], [34]).

Rule 1 (Min Plus One).

$$P(v) \leftarrow \min_{u \in \mathcal{N}(v)} \{P(u)\} + 1.$$

The idea is that just before the pulse number is changed, the node sends out all the messages of previous rounds, which have not been sent yet. Note, that since $v \in \mathcal{N}(v)$, we have $\min_{u \in \mathcal{N}(v)} \{P(u)\} \leq P(v)$ and, hence, $P(v)$ cannot increase by more than 1 in a single application of Rule 1. This has the nice consequence that each node goes through all pulse numbers, as expected.

Stabilization issues. As is well known, Rule 1 is *stable*; that is, if the configuration is legal (as in Definition 3.1), then applying the rule arbitrarily can yield only a legal configuration. Notice, however, that if the state is not legal, then applying Rule 1 may cause pulse numbers to drop. This is something to worry about, since the regular course of the algorithm requires pulse numbers only to grow. Thus, it is conceivable that actions taken in legal neighborhoods are adversely affected by the actions taken in illegal neighborhoods. This intuition is captured by the following theorem.

Theorem 3.1. *Rule 1 is not self-stabilizing.*

Proof. The proof is by a counterexample. Consider the pulse configuration of a 10-node ring, as depicted in Fig. 1a. The vertical edges represent illegal links. Consider now the execution described in Figs. 1a, 1b, 1c, 1d, 1e, 1f, 1g, 1h, and 1i, obtained by the repeated application of Rule 1. It is readily seen that the last configuration (Fig. 1i) is, basically, identical to the configuration in Fig. 1a, with all the pulse numbers incremented by 1, and rotated one step counterclockwise. Repeating this schedule results in an infinite execution, in which each processor takes infinitely many steps, but none of the configurations is legal. \square

Let us make a short digression here. The above leads also to an interesting observation for *clock synchronization*: One of the popular schemes for clock synchronization [40] is “repeated averaging.” Roughly speaking, under the repeated averaging rule, each node sets its value to be the average value of its neighbors but advances the clock if this average is close enough to its own value.

Observation 3.2. *Repeated averaging does not stabilize.*

Proof sketch. The scenario in the proof of Theorem 3.1 shows that averaging with rounding down does not work. A similar scenario can be constructed for averaging with rounding up.

Time complexity issues. Consider Fig. 1a. Note, that the illegal state manifests in the fact that the nodes with the minimum clock values have value gaps with their neighbors (1 versus 3). Intuitively, one would hope that the illegal

Fig. 2. A pulse assignment for Rule 2.

state is resolved by the fact that the nodes with the minimum value increment their clocks and catch up with the others. Looking at Fig. 1i, the nodes with the minimum values indeed incremented their clocks. However, other nodes decreased the values of their clocks and became the new minima. Moreover, the illegal state in Fig. 1 (Fig. 1i) manifests again in the gap in the values between these minimum nodes and their neighbors (2 versus 4).

One idea that can pop into mind in trying to repair the flaw exposed by the proof on the previous page is never letting pulse numbers go down. A similar rule appears in [28] (except for the case of a wraparound of the bounded clock). In [31] (Section 5), such a rule is suggested as a modification that makes the rule in [26] self-stabilizing. Formally, the rule is the following:

Rule 2 (Monotone Min Plus One).

$$P(v) \leftarrow \max \left\{ P(v), \min_{u \in \mathcal{N}(v)} \{P(u)\} + 1 \right\}.$$

Rule 2 can be proven to be self-stabilizing. However, it suffers from a serious drawback regarding its stabilization time. Consider the configuration depicted in Fig. 2.

A quick thought should suffice to convince the reader that the stabilization time for this configuration using Rule 2 is about 1,000,000 time units, which seems to be unsatisfactory for such a small network. This example demonstrates an important property that we shall require from any self-stabilizing protocol: The stabilization time must not depend on the initial state; rather, it should be bounded by a function of the network topology. A clear lower bound on the stabilization time is the diameter of the network. In the example above, using Rule 2, the stabilization time depends linearly on the value of the pulses, thus implying that the stabilization time can be arbitrarily large.

Asynchrony issues. The next idea is to have a combination of rules: Certainly, if the neighborhood is legal, then the problem specification requires that Rule 1 is applied. However, if the neighborhood is not legal, then another rule can be used. The first idea that we consider is the following *Maximum* rule for the case that a node detects locally that the network is not stable. A similar rule is used in [31], [11], [20] in the context of synchronous networks.

Rule 3 (Maximum).

$$P(v) \leftarrow \begin{cases} \min_{u \in \mathcal{N}(v)} \{P(u)\} + 1, & \text{if } legal(v) \\ \max_{u \in \mathcal{N}(v)} \{P(u), P(v)\}, & \text{otherwise.} \end{cases}$$

It is straightforward to show that if an atomic action consists of a node reading its neighbors and setting its own value (in particular, no neighbor changes its value in the meantime), then Rule 3 above converges to a legal configuration. Unfortunately, this model, traditionally called the *central daemon* [19], [14], requires tight synchronization between

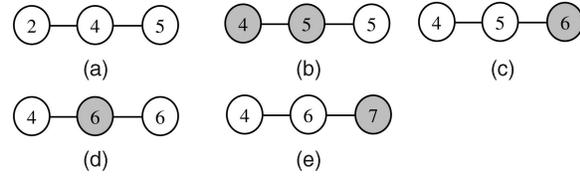

Fig. 3. An execution using Rule 3 in a truly distributed system. The node that sends or receives in each step is marked.

nodes, which is not considered realistic usually. As shown in [31], [11], a similar rule suffices even without such an atomic action, but assuming a synchronous network. Unfortunately, Rule 3 does not work in asynchronous networks without a central daemon.

Theorem 3.3. *Rule 3 is not self-stabilizing in an asynchronous system.*

Proof. A scenario where the system does not self-stabilize is given in Fig. 3. The move from the configuration in Fig. 3c to that in Fig. 3d may seem surprising. However, in an asynchronous environment, the message that the left node increased its clock value from 2 to 4 (moving from Fig. 3a to Fig. 3b) may be slower than messages from the node on the right. In this case, the estimation at the middle node of the value of the left node in the configuration in Fig. 3c is 2. The middle node then applies the correcting part of Rule 3, resulting in yet another illegal configuration (Fig. 3d). Since the configuration in Fig. 3e is equivalent to the configuration in Fig. 3a, with pulse numbers incremented by 2, we conclude that repeating this schedule results in an execution with infinitely many illegal states. □

Locality and simplicity issues. Finally, we would like to address two properties that are somewhat harder to capture formally: *locality and simplicity*. It seems, however, that these properties are of the highest importance in practice. The rules discussed above exhibit these properties, even though each such rule had other disadvantages. In mending the above rules, we should not spoil the locality and simplicity that they exhibit.

By *locality* we mean that it is much preferable that a processor will be able to operate while introducing only the minimal possible interference with other nodes in the network. In other words, invoking a global operation is considered costly, and we would like to avoid it as much as possible. One way to capture this intuition approximately in our case is to require that the only state information at the nodes is the pulse number and that protocols should operate by applying local rules as above.

As an illustrative exercise, contrast this approach with the following solution: Whenever an illegal state is detected, *reset* the whole system. This solution, although it may be unavoidable in some cases, does not seem particularly appealing as a routinely activated procedure. Consider, for example, the common situation in which a new node joins the system (perhaps, it was down for some time). We would like the protocols to feature *graceful joining* in this case, that is, that other nodes would be affected only if necessary (for example, the neighbors). Note, that a rule that reduces the value of a clock always to the minimum among the neighbors will not handle such a join gracefully, even if no reset is used. That is, the joining node may have a zero

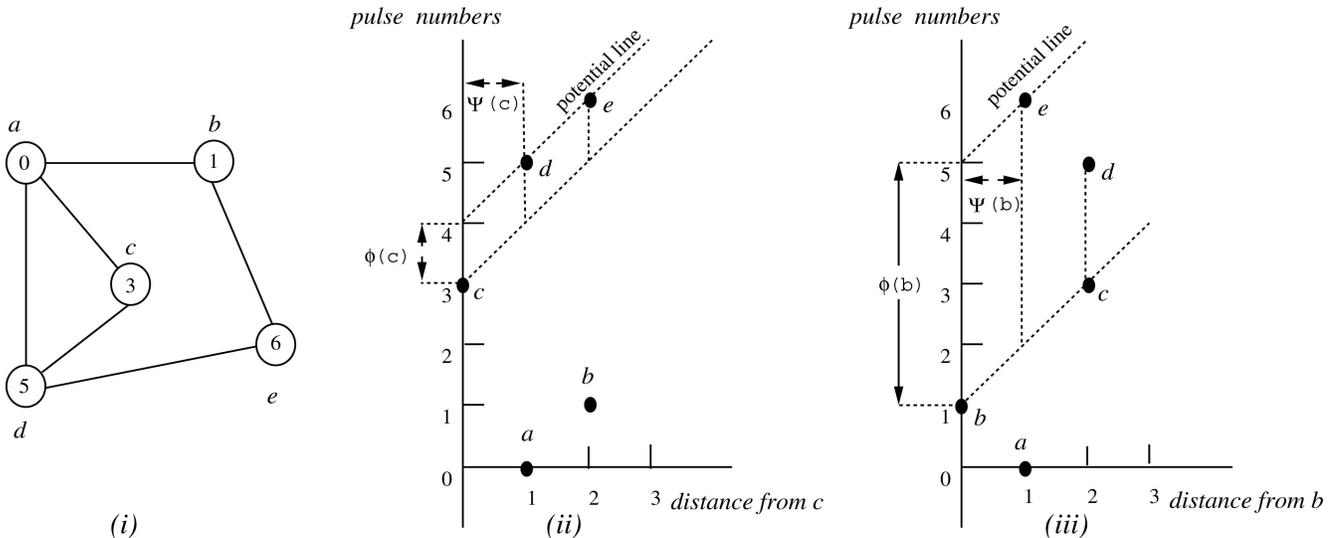

Fig. 4. (a) An example of a graph with pulse assignment. Geometrical representations of this configuration are shown in (b) and (c). (b) The plane corresponding to node c is shown, and (c) the plane corresponding to node b is shown. As can be readily seen, $\phi(c) = 1$ and $\phi(b) = 4$. Also, $\Psi(c) = 1$ and $\Psi(b) = 1$ (see Definition 4.2).

value for its pulse. A rule such as Rule 1 can cause all the nodes in the network to reduce the values of their clocks significantly.

The last property that we require from distributed protocols is even harder to define precisely. Essentially, we would like to have the protocols conceptually *simple*. This will make the protocols easy to understand and, therefore, easy to implement and maintain. This requirement is one of the main obstacles for many sophisticated protocols that are not used in practice.

4 AN OPTIMAL SELF-STABILIZING RULE

In this section, we give a simple self-stabilizing optimal rule of synchronization and analyze its stabilization time. Specifically, our synchronization scheme is based on the following rule.

Rule 4 (Max Minus One).

$$P(v) \leftarrow \begin{cases} \min_{u \in \mathcal{N}(v)} \{P(u)\} + 1, & \text{if legal}(v) \\ \max_{u \in \mathcal{N}(v)} \{P(u) - 1, P(v)\}, & \text{otherwise.} \end{cases}$$

In words, Rule 4 requires applying a “minimum-plus-one” rule (Rule 1) when the neighborhood seems to be in a legal configuration and if the neighborhood seems to be illegal to apply a “maximum-minus-one” rule (but never decrease the pulse number). The similarity to the “maximum” rule (Rule 3) is obvious. The intuition behind the modification is that if nodes change their pulse numbers to be the *maximum* of their neighbors, then “race conditions” might evolve, where nodes with high pulse numbers can “run away” from nodes with low pulse numbers. Since the correction action takes the pulse number to be 1 less than the maximum, nodes with high pulse number are “locked,” in the sense that they cannot increment their pulse counters until all in their neighborhood have reached their pulse number. This “locking” spreads automatically in all the “infected” area of the network. Formally, the way Rule 4

corrects any initial state is analyzed in detail in the proof of Theorem 4.1.

Theorem 4.1. *Let $G = (V, E)$ be a graph with diameter d and $P : V \rightarrow \mathbb{N}$ be a pulse assignment. Then, applying Rule 4 above results in a legal configuration in at most d time units.*

In order to prove Theorem 4.1, we develop some tools to analyze the behavior of the synchronization scheme. The basic concept that we use is a certain *potential* value that we associate with every node, described in the following definition.

Definition 4.1. *Let v be a node in the graph. For any node u , the wave height of u over v is*

$$D_v(u) = P(u) - P(v) - \text{dist}(u, v).$$

The *potential* of v , denoted $\phi(v)$, is

$$\phi(v) = \max_{u \in V} \{D_v(u)\}.$$

Intuitively, $D_v(u)$ measures by how much the pulse number of v is lagging behind the pulse number of u , after allowing for a correction due to the distance between them. The potential $\phi(v)$ is a measure of the largest distance-adjusted skew in the synchronization of v . Graphically, one can think that every node u is a point on a plane, where the x -coordinate represents the distance of u from v , and the y -coordinate represents the pulse numbers (see Fig. 4 for an example). In this representation, v is at the origin (and it is the only node on the line $x = 0$), $D_v(u)$ is the vertical distance between u and the 45-degree line from the origin, and $\phi(v)$ is the maximal vertical distance $D(u)$ of any point (that is, node u) above the 45-degree line $y(x) = P(v) + x$.

Let us start with a few simple properties of ϕ .

Lemma 4.2. *For all nodes $v \in V$, $\phi(v) \geq 0$.*

Proof. By definition, $\phi(v) \geq D_v(v) = 0$. \square

Lemma 4.3. *A configuration of the system is legal if and only if for all $v \in V$, $\phi(v) = 0$.*

Proof. Suppose first that $\phi(v) = 0$ for all v . Then, in particular, for each edge (u, v) , we have

$$P(u) - P(v) = D_v(u) + 1 \leq \phi(v) + 1 = 1,$$

and, similarly, $P(v) - P(u) \leq 1$. That is, the difference between the pulse numbers of every pair of neighbors is at most 1, so the configuration is legal. Conversely, suppose now that $\phi(v) > 0$ for some node v . Then, for some node u , $D_v(u) > 0$, that is, $P(u) - P(v) > \text{dist}(u, v)$. Pick any path from u to v of length $\text{dist}(u, v)$. Since the difference in the pulse assignments in the end points is larger than the number of links along the path, by the pigeonhole principle, there must exist a link (w, y) on the path such that $P(y) - P(w) > 1$ and, hence, the configuration is illegal. \square

So far, we analyzed a given configuration in terms of the values of the pulse counters at the nodes. We now turn to analyze the way configurations change dynamically over time. To this end, we must consider the effect of the asynchronous schedule. In particular, at any given instant, the value of a pulse counter at a node may not necessarily be its value as perceived by its neighbor. We denote the pulse value of a node x as perceived by its neighbor y by $P_x(y)$. Another notational convention that we adopt is that when we talk about two states where one occurs before the other, we denote all functions of the later state by a prime; for example, $\phi(v)$ is the potential of v in the first state, and $\phi'(v)$ is the potential of v in the later state.

To facilitate the analysis, we first state the self-stabilization property that we assume on the links.

Lemma 4.4. *Suppose that the computation starts in an arbitrary state. Consider the sequence of pulse values $P_u(w)$ read by a node u from a neighbor w and the sequence of $P(w)$ values in node w . Then, with the possible exception of a prefix of at most T_0 time units, these sequences are identical and, moreover, every value of $P(w)$ appears as a value of $P_u(w)$ after at most one time unit.*

For the remainder of the discussion, we will identify the start of the computation with the aforementioned T_0 ; that is, our analysis assumes that the links have already stabilized.

The following lemma is the key to dealing with an asynchronous schedule.

Lemma 4.5. *For all neighbors u and v at all times, we have $P_v(u) \leq P(u)$.*

Proof. The proof follows from Lemma 4.4, and the fact that the sequence of pulse numbers in a node is nondecreasing. \square

Lemma 4.6. *Consider a given state and suppose that some node u changes its pulse number by applying Rule 4. Then, for all nodes $v \in V$, $\phi'(v) \leq \phi(v)$.*

Proof. The first easy case to consider is the potential of u itself. Since by Lemma 4.5, $P'(u) > P(u)$ in this case, we have

$$\begin{aligned} \phi'(u) &= \max_{w \in V} \{P'(w) - P'(u) - \text{dist}(w, u)\} \\ &\leq \max \left(\max_{w \neq u} \{P(w) - \text{dist}(w, u) - P'(u)\} 0 \right) \\ &\leq \max_{w \in V} \{P(w) - P(u) - \text{dist}(w, u)\} \\ &= \phi(u). \end{aligned}$$

Let us now consider $v \neq u$. The only value that was changed in the set $\{D_v(w) | w \in V\}$ is $D_v(u)$. We prove that $D'_v(u) \leq D_v(w)$ for some $w \in \mathcal{N}(u)$ and, hence, $\phi'(v) \leq \phi(v)$. There are two cases to consider. First, assume that u changed its pulse by applying the “min plus one” part of Rule 4. Since $u \neq v$, there must be a node $w \in \mathcal{N}(u)$, with $\text{dist}(w, v) = \text{dist}(u, v) - 1$. Also, since “min plus one” was applied, and using Lemma 4.5, we have $P'(u) \leq P_u(w) + 1 \leq P(w) + 1$. Therefore,

$$\begin{aligned} D'_v(u) &= P'(u) - P(v) - \text{dist}(u, v) \\ &\leq (P(w) + 1) - P(v) - (\text{dist}(w, v) + 1) \\ &= P(w) - P(v) - \text{dist}(w, v) \\ &= D_v(w) \end{aligned}$$

and, hence, $\phi'(v) \leq \phi(v)$ in this case.

The second case to consider is when u has changed its value by applying the “max minus one” part of Rule 4. The reasoning is dual to the first case. Let w be a neighbor of u such that $P_u(w) = \max\{P_u(r) | r \in \mathcal{N}(u)\}$. Then, using Lemma 4.5, we have $P(w) \geq P_u(w) = P'(u) + 1$. By the triangle inequality, $\text{dist}(w, v) \leq \text{dist}(u, v) + 1$ and, hence,

$$\begin{aligned} D'_v(u) &= P'(u) - P(v) - \text{dist}(u, v) \\ &\leq (P(w) - 1) - P(v) - (\text{dist}(w, v) - 1) \\ &= P(w) - P(v) - \text{dist}(w, v) \\ &= D_v(w) \end{aligned}$$

and we are done. \square

In particular, each time a node with a positive potential changes its pulse number, its potential strictly decreases. This fact, when combined with Lemmas 4.2 and 4.3, can be used to prove eventual stabilization. However, this argument only shows that the stabilization time is bounded by the total potential of the configuration, which, in turn, depends on the initial pulse assignment. We need a stronger argument in order to prove a bound on the stabilization time that depends only on the topology, as asserted in Theorem 4.1. Toward this end, we define the notion of “wave front.”

Definition 4.2. *Let v be any node. The wave of v , denoted $W(v)$, is the set*

$$W(v) = \{u \in V | D_v(u) = \phi(v)\}.$$

The wave front distance of v , denoted $\Psi(v)$, is defined by

$$\Psi(v) = \min\{\text{dist}(u, v) | u \in W(v)\}.$$

In the graphical representation, the wave front distance of a node is simply the distance to the closest node on the “potential line” (see Fig. 4 for an example). Intuitively, one can think of $\Psi(v)$ as the distance to the “closest clock that is maximum too far ahead” of v . The importance of the wave front becomes apparent in Lemma 4.10, but let us first state its immediate property.

Lemma 4.7. *Let $v \in V$. Then, $\Psi(v) = 0$ if and only if $\phi(v) = 0$.*

The following lemma captures the “locking effect” of the “max minus one” part of Rule 4.

Lemma 4.8. *Suppose that at a given state, $\phi(v) > 0$, and $u \in W(v)$. Then, applying Rule 4 does not change the pulse number at u .*

Proof. First, we claim that for all $w \in \mathcal{N}(u)$, we have $P(w) \leq P(u) + 1$ because

$$\begin{aligned} P(w) &= D_v(w) + P(v) + \text{dist}(v, w) \\ &\leq D_v(u) + P(v) + \text{dist}(v, u) + 1 = P(u) + 1. \end{aligned}$$

It follows that any application of the “max minus one” part of Rule 4 cannot increase the number at u . As for the “min plus one” part, suppose that all links incident to u are legal. Observe that $u \neq v$ because $\phi(v) > 0$. Let $w \in \mathcal{N}(u)$ be such that $\text{dist}(v, w) = \text{dist}(v, u) - 1$; that is, w is on the shortest path from v to u . Since $u \in W(v)$, we have $D_v(w) \leq D_v(u)$ and, hence,

$$\begin{aligned} P(w) &= D_v(w) + P(v) + \text{dist}(v, w) \\ &\leq D_v(u) + P(v) + \text{dist}(v, u) - 1 = P(u) - 1. \end{aligned}$$

Therefore, if u applies the “min plus one” part of Rule 4, then the resulting pulse number cannot be more than $P(w) + 1 = P(u)$; that is, $P(u)$ remains unchanged. \square

The following lemma states that $W(v)$ is monotonically growing, so long as the potential of v is positive.

Lemma 4.9. *Suppose that at a given state, $u \in W(v)$. If in the following state, $\phi'(v) > 0$, then $u \in W'(v)$.*

Proof. Suppose that node x applied Rule 4 between the two states. By Lemma 4.8, if $x = u$, then the state remains unchanged, and the lemma follows trivially. If $x = v$, then for all nodes, $w \neq v$, $D'_v(w) = D_v(w) - (P'(v) - P(v))$; that is, all D_v values are decreased by the same amount (which is exactly the increase in the pulse number of v). Therefore, $D'_v(u)$ remains maximal among $D'_v(w)$ values for $w \neq v$. If $\phi'(v) > 0$, then $D'_v(u) > D'_v(v)$ and, hence, $u \in W'(v)$. Finally, suppose that $x \notin \{u, v\}$ moved. In this case, $D'_v(u)$ does not change and, hence, $\phi'(v) = \phi(v)$ by Lemma 4.6. It follows that $u \in W'(v)$ in this case too. \square

Lemma 4.10. *Suppose that at a given state, we have $\Psi(v) > 0$. Then, after one time unit, we have $\Psi'(v) \leq \Psi(v) - 1$.*

Proof. Suppose $\Psi(v) = f > 0$ at the given state. If after one time unit, we have $\phi'(v) = 0$, then we are done, since in this case, $\Psi'(v) = 0$ by Lemma 4.7. Thus, assume henceforth that $\phi'(v) > 0$. Consider any node $u \in W(v)$ such that $\text{dist}(u, v) = \Psi(v)$. Let $\text{closer}_v(u) \in \mathcal{N}(u)$ be such that $\text{dist}(v, \text{closer}_v(u)) = f - 1$; that is, $\text{closer}_v(u)$ is on the shortest path from v to u . Note, that such a node $\text{closer}_v(u)$ must exist because $\Psi(v) > 0$ and, hence, $u \neq v$. We claim that after one time unit, $P'(\text{closer}_v(u)) \geq P(u) - 1$. To see that, first note that at the given state, $P(\text{closer}_v(u)) \leq P(u) - 1$ because $\text{closer}_v(u) \notin W(v)$ (otherwise, $\Psi(v)$ would have been at most $f - 1$). This means that the link $(\text{closer}_v(u), u)$ is in an illegal state. Therefore, after at most one time unit, $\text{closer}_v(u)$ will read the pulse number of v , and by Rule 4, this will set its pulse number to be at least $P(u) - 1$. It follows that after one time unit, for each node in $u \in W(v)$, there exists a node $\text{closer}_v(u)$, which is closer to v by one unit and whose pulse number is at least

$P(u) - 1$, which means that $D'_v(\text{closer}_v(u)) \geq D'_v(u)$. Since by Lemma 4.9, $u \in W'(v)$, we must also have $\text{closer}_v(u) \in W'(v)$ and, therefore, $\Psi'(v) \leq \Psi(v) - 1$. \square

The next corollary follows from Lemma 4.7 and an inductive application of Lemma 4.10.

Corollary 4.11. *Let v be any node. Then, after at most $\Psi(v)$ time units, $\phi(v) = 0$.*

We can now prove Theorem 4.1.

Proof of Theorem 4.1. By Lemma 4.3, it suffices to show that after at most d time units, $\phi(v) = 0$ for all $v \in V$. From Corollary 4.11, we actually know that a slightly stronger fact holds: for all nodes $v \in V$, after at most $\Psi(v)$ time units, $\phi(v) = 0$. The theorem follows from the facts that for all $v \in V$, $\Psi(v) \leq d$, and by the fact that $\phi(v)$ never increases by Lemma 4.6. \square

It is straightforward to see that starting in a legal configuration, every application of Rule 4 leaves the system in a legal configuration, as long as no additional faults occur. Clearly, our Rule 4 satisfies the synchronization condition; that is, any message sent at local pulse i is delivered at the other end point before its local pulse $i + 1$ (see discussion after Definition 3.1). Finally, note that our synchronizer has progress rate 1 and network slack equal to the diameter of the network.

5 CONCLUSION

Many of the related papers deal with aspects that are not studied in the current paper. Below, we mention some such issues and discuss how they may be relevant to our paper or to future research.

The tool proposed here seems to motivate the research about composition between self-stabilizing protocols to obtain a good time complexity. Specifically, one may want to use a reset procedure, together with the algorithm proposed here, in order to make the result work for bounded clocks. Such a specific kind of composition was discussed in [8], as well as in the original version of this paper, but only for the task at hand. This issue was later developed in a wider context in other papers such as [22]. It seems that there are still interesting open questions in this area.

In this paper, we devised a phase clock as a method to synchronize networks in a self-stabilizing manner. As noted in [16], [26], [20], [31], [11], a phase clock has many other applications. An interesting question is whether better algorithms exist for specific applications. In particular, should one need a synchronizer only (the application discussed in this paper), does there exist better algorithms for that problem (better than for the asynchronous phase clock problem)? For example, multiple papers dealt with the issue of bounding the size of the phase clock. Given a lower bound on the size of phase clocks, does this lower bound apply to the problem of constructing a self-stabilizing synchronizer?

As mentioned above, a trivial solution of one state exists in *synchronous* networks. However, such a solution is not useful (beyond the service that a synchronous network provides anyhow). It was shown in [39] that no deterministic clock algorithm for a clock with a constant number of bits exists. It was mentioned in [11] that their scheme needs $\Omega(n)$ states in some graph in order not to deadlock. Note that any local scheme (incrementing the value of the clock

based only on the value of the clocks of a node and its neighbors) must use Rule 1 in cases where the clock values are legal. Since this is the rule used in [11], there exist graphs where the size of the clock is bounded from below by $\Omega(n)$ for “local” schemes (as shown in [16], there exist smaller clocks in many graphs). Does this lower bound apply to local schemes for a self-stabilizing synchronizer? What is the minimum size of a clock if the algorithm is not required to be local (in the sense mentioned above)? It seems likely that such a nonlocal algorithm may consume more time between pulses. Is there a time-rate trade-off? Moreover, our time optimal algorithm is not space optimal. Does there exist an algorithm that is optimal in all the parameters?

Several papers deal with models that allow additional kinds of faults such as *crash* faults, *napping* faults, and *Byzantine* faults. For example, see [24], [25], [20], [46]. One can ask what the optimal stabilization time in these models is. Is it inherently larger than the model of self-stabilization?

ACKNOWLEDGMENTS

A preliminary version of this paper was included in an extended abstract that was presented at the Twenty-Fifth Annual ACM Symposium on Theory of Computing.

Baruch Awerbuch received the PhD degree from the Technion-Israel Institute of Technology, Haifa, Israel, in 1984. He is a professor of computer science at Johns Hopkins University. From 1984 to 1994, he was with the Department of Mathematics, Massachusetts Institute of Technology, as a postdoctoral fellow, a research associate, and a faculty member. His research interests include algorithms, wireless networks, learning, security, and peer-to-peer systems,

with the emphasis on algorithmic approaches to real systems and networks.

Shay Kutten received the PhD degree in computer science from the Technion-Israel Institute of Technology, Haifa, Israel, in 1987. From 1987 to 2000, he was with the IBM T.J. Watson Research Center as a postdoctoral fellow, a project leader, the manager of the Network Architecture and Algorithms Group and of Distributed Systems Security, and a research staff member. He led the network security project, which developed the security architecture for several IBM products, and developed algorithms for network control, security, and distributed processing control that were later used in IBM's products. He was the head of the Information Systems Area and the coordinator of undergraduate studies of the William Davidson Faculty of Industrial Engineering and Management, Technion. He was also a member of the editorial board of the *ACM Wireless Networks* and of the Elsevier journal *Computer Networks*. He chaired the program committees of the 12th International Symposium on Distributed Computing (DISC '98) and of the 23rd Annual ACM Symposium on Principles of Distributed Computing (PODC '04). He is an area editor (for security, reliability, and availability) of the *ACM Mobile Networks and Applications*. He received the Taub Award for excellence in research and the Mitchner Award for research on quality sciences and quality management. He is the recipient of the 1993 and 1994 IBM Outstanding Innovation Awards (OIA) for his work on distributed control protocols, which were the basis to the distributed control of IBM Broad Band Networking Services architecture NBBS, and for his work on authentication protocols and his contributions to IBM's network security and NetSP (by itself an award winning product). The same authentication protocols influenced the later development of the Internet payment protocol, so IBM had to grant a no-fee license so that the Internet could adopt this payment protocol.

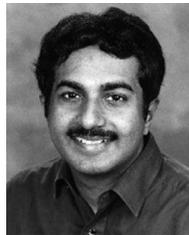

From 1984 to 1994, he was with the Department of Mathematics, Massachusetts Institute of Technology, as a postdoctoral fellow, a research associate, and a faculty member. His research interests include algorithms, wireless networks, learning, security, and peer-to-peer systems,

Yishay Mansour received the BA and MSc degrees from the Technion-Israel Institute of Technology, Haifa, Israel, in 1985 and 1987, respectively, and the PhD degree from the Massachusetts Institute of Technology in 1990. Following that, he was a postdoctoral fellow at Harvard University and a research staff member at the IBM T.J. Watson Research Center. Since 1992, he has been with the School of Computer Science, Tel-Aviv University, where he was the chairman from 2000 to 2002. He has supervised more than a dozen graduate students, served on numerous program committees, and is currently an editor in four leading journals. He has written numerous papers in all areas of computer science, with special emphasis on communication networks, machine learning, reinforcement learning, computational game theory, and algorithm design.

Boaz Patt-Shamir received the BSc degree from Tel Aviv University, the MSc degree from the Weizmann Institute of Science, and the PhD degree in 1995 from the Massachusetts Institute of Technology. He was an assistant professor at Northeastern University and then joined the Department of Electrical Engineering, Tel Aviv University, where he directs the Distributed Computation Laboratory.

George Varghese received the PhD degree from the Massachusetts Institute of Technology in 1992. Before that, he worked at Digital Equipment Corp. for several years, designing DECNET protocols and products (bridge architecture, Gigaswitch). He worked from 1993 to 1999 at Washington University. He joined the University of California, San Diego in 1999, where he currently is a professor of computer science. In May 2004, he cofounded NetSift Inc.

(now part of Cisco Systems), where he was the president and chief technical officer. From August 2005 to August 2006, he worked at Cisco Systems to help equip future routers and switches to detect traffic patterns to facilitate traffic measurement and real-time intrusion detection. Several of the algorithms that he has helped develop have found their way into commercial systems including Linux (timing wheels), the Cisco GSR (DRR), and Microsoft Windows (IP lookups). He also helped design the lookup engine for Procket's 40 Gbps forwarding engine. He has written a book on building fast router and end-node implementations entitled *Network Algorithmics* (Morgan-Kaufman, 2004). He is a fellow of the ACM. He received the US Office of Naval Research (ONR) Young Investigator Award in 1996. Together with colleagues, he holds 14 patents awarded in the general field of network algorithmics.
