Local Light Field Fusion:
Practical View Synthesis with Prescriptive Sampling Guidelines

Fig. 1. We present a simple and reliable method for view synthesis from a set of input images captured by a handheld camera on an irregular grid pattern. We theoretically and empirically demonstrate that our method enjoys a prescriptive sampling rate that requires fewer input views than Nyquist for high-fidelity view synthesis of natural scenes. Specifically, we show that this rate can be interpreted as a requirement on the pixel-space disparity of the closest object to the camera between captured views (Section 3). After capture, we expand all sampled views into layered representations that can render high-quality local light fields. We then blend together renderings from adjacent local light fields to synthesize dense paths of new views (Section 4). Our rendering consists of simple and fast computations (homography warping and alpha compositing) that can generate new views in real-time.

We present a practical and robust deep learning solution for capturing and rendering novel views of complex real world scenes for virtual exploration. Previous approaches either require intractably dense view sampling or provide little to no guidance for how users should sample views of a scene to reliably render high-quality novel views. Instead, we propose an algorithm for view synthesis from an irregular grid of sampled views that first expands each sampled view into a local light field via a multiplane image (MPI) scene representation, then renders novel views by blending adjacent local light fields. We extend traditional plenoptic sampling theory to derive a bound that specifies precisely how densely users should sample views of a given scene when using our algorithm. In practice, we apply this bound to capture and render views of real-world scenes that achieve the perceptual quality of Nyquist rate view sampling while using up to fewer views. We demonstrate our approach’s practicality with an augmented reality smartphone app that guides users to capture input images of a scene and renders novel views at up to 720p resolution in real-time.

Additional Key Words and Phrases: view synthesis, plenoptic sampling, light fields, image-based rendering, deep learning

1 INTRODUCTION

The most compelling virtual experiences completely immerse the viewer in a scene, and a hallmark of such experiences is the ability to view the scene from a close interactive distance. This is currently possible with synthetically rendered scenes, but this level of intimacy has been very difficult to achieve for virtual experiences of real world scenes.
Ideally, we could simply sample the scene’s light field and interpolate the relevant captured images to render new views. Such light field sampling strategies are particularly appealing because they pose the problem of image-based rendering (IBR) in a signal processing framework where we can directly reason about the density and pattern of sampled views required for any given scene. However, Nyquist rate view sampling is intractable for scenes with content at interactive distances, as the required view sampling rate increases linearly with the reciprocal of the closest scene depth. For example, for a scene with a subject at a depth of 0.5 meters, captured by a mobile phone camera with a 64° field of view, and rendered at 1 megapixel resolution, the required sampling rate is an intractable 2.5 million images per square meter. Since it is not feasible to capture all the required images, the IBR community has moved towards view synthesis algorithms that leverage geometry estimation to predict the missing views.

State-of-the-art algorithms pose the view synthesis problem as the prediction of novel views from an unstructured set or arbitrarily sparse grid of input camera views. While the generality of this problem statement is appealing, abandoning a plenoptic sampling framework sacrifices the crucial ability to rigorously reason about the view sampling requirements of these methods and predict how their performance will be affected by the input view sampling pattern. When faced with a new scene, users of these methods are limited to trial-and-error to figure out whether a set of sampled views will produce acceptable results for a virtual experience.

Instead, we propose a view synthesis approach that is grounded within a plenoptic sampling framework and can precisely prescribe how densely a user must capture a given scene for reliable rendering performance. Our method is conceptually simple and consists of two main stages. We first use a deep network to promote each source view to a layered representation of the scene that can render a limited range of views, advancing recent work on the multiplane image (MPI) representation [Zhou et al. 2018]. Next, we blend between adjacent layered renderings to render novel views.

Our theoretical analysis shows that the number of views required by our method decreases quadratically with the number of planes we predict for each layered scene representation, up to limits set by the camera field of view. We empirically validate our analysis and apply it in practice to render novel views with the perceptual quality of Nyquist view sampling while using up to $4^2 \approx 4000\times$ fewer images.

It is impossible to break the Nyquist limit with full generality for arbitrary unnatural scenes, but we show that it is possible to achieve Nyquist level performance with greatly reduced view sampling by specializing to the subset of natural scenes. This capability is primarily due to our high quality local light field estimation by a deep learning pipeline trained on renderings of natural scenes, and our use of an intermediate layered scene representation that ensures consistency among local views.

In summary, our key contributions are:

1. An extension of plenoptic sampling theory that directly specifies precisely how users should sample input images for reliable high quality view synthesis with our method.

2. A practical and robust solution for capturing and rendering complex real world scenes for virtual exploration.

3. A demonstration that carefully crafted deep learning pipelines using local layered scene representations achieve state-of-the-art view synthesis results.

We extensively validate our derived prescriptive view sampling requirements and demonstrate that our algorithm quantitatively outperforms traditional light field reconstruction methods as well as state-of-the-art view interpolation algorithms across a range of sub-Nyquist view sampling rates. We highlight the practicality of our method by developing an augmented reality app that implements our derived sampling guidelines to help users capture input images to produce reliably high-quality renderings with our algorithm. Additionally, we develop mobile and desktop viewer apps that render novel views from our predicted layered representations in real-time. Finally, we qualitatively demonstrate that our algorithm reliably produces state-of-the-art results across a diverse set of complex real-world scenes.

2 RELATED WORK

Image-based rendering (IBR) is the fundamental computer graphics problem of rendering novel views of objects and scenes from sampled views. We find that it is useful to categorize IBR algorithms by the extent to which they use explicit scene geometry, as done by Shum and Kang [2000].

2.1 Plenoptic Sampling and Reconstruction

Light field rendering [Levoy and Hanrahan 1996] eschews any geometric reasoning and simply samples images on a regular grid so that new views can be rendered as slices of the sampled light field. Lumigraph rendering [Gortler et al. 1996] showed that using approximate scene geometry can ameliorate artifacts due to undersampled or irregularly sampled views.

The plenoptic sampling framework [Chai et al. 2000] analyzes light field rendering using signal processing techniques, showing that the Nyquist view sampling rate for light fields depends on the minimum and maximum scene depths. Furthermore, they discuss how the Nyquist view sampling rate can be lowered with more knowledge of scene geometry. Zhang and Chen [2003] extend this analysis to show how non-Lambertian and occlusion effects increase the spectral support of a light field, and also propose more general view sampling lattice patterns.

Rendering algorithms based on plenoptic sampling enjoy the significant benefit of prescriptive sampling; given a new scene, it is easy to compute the required view sampling density to enable high-quality renderings. Many modern light field acquisition systems have been designed based on these principles, including large-scale camera systems [Overbeck et al. 2018; Wilburn et al. 2005] and a mobile phone app [Davis et al. 2012].

We posit that prescriptive sampling is necessary for practical and useful IBR algorithms, and we extend prior theory on plenoptic sampling to show that our deep-learning-based view synthesis strategy can significantly decrease the dense sampling requirements of traditional light field rendering. Our novel view synthesis pipeline can also be used in future light field acquisition hardware systems to reduce the number of required cameras.
2.2 Geometry-Based View Synthesis

Many IBR algorithms attempt to leverage explicit scene geometry in efforts to synthesize new views from arbitrary unstructured sets of input views. These approaches can be meaningfully categorized as either using global or local geometry.

Techniques that use global geometry generally compute a single global mesh from a set of unstructured input images. Simply texture mapping this global mesh can be effective for constrained situations such as panoramic viewing with mostly rotational and little translational viewer movement [Hedman et al. 2017; Hedman and Kopf 2018], but a major shortcoming is that they can only simulate Lambertian materials. Surface light fields [Wood et al. 2000] are able to render convincing view-dependent effects, but require accurate geometry from dense range scans and hundreds of captured images to sample the outgoing radiance from points on an object’s surface.

Many free-viewpoint IBR algorithms are based upon a strategy of locally texture mapping a global mesh. The influential view-dependent texture mapping algorithm [Debevec et al. 1996] proposed an approach to render novel views by blending nearby captured views that have been reprojected using a global mesh. Work on Unstructured Lumigraph Rendering [Buehler et al. 2001] focused on computing per-pixel blending weights for reprojected images and proposed a heuristic algorithm that satisfied key properties for high-quality rendering. Unfortunately, it is very difficult to estimate high-quality meshes whose geometric boundaries align well with image edges, and IBR algorithms based on global geometry typically suffer from significant artifacts. State-of-the-art algorithms [Hedman et al. 2018, 2016] attempt to remedy this shortcoming with complicated pipelines that involve both global mesh and local depth map estimation. However, it is difficult to precisely define view sampling requirements for robust mesh estimation, and the mesh estimation procedure typically takes multiple hours, so this strategy is impractical for casual content capture scenarios.

IBR algorithms that use local geometry [Chaurasia et al. 2013; Chen and Williams 1993; Kopf et al. 2013; McMillan and Bishop 1995; Ortiz-Cayon et al. 2015] avoid difficult and expensive global mesh estimation. Instead, they typically compute local detailed geometry for each input image and render novel views by reprojecting and blending nearby input images. The state-of-the-art Soft3D algorithm [Penner and Zhang 2017] blends between reprojected local layered representations to render novel views, which is conceptually similar to our strategy. However, Soft3D computes each local layered representation by aggregating heuristic measures of depth uncertainty over a large neighborhood of views. We instead train a deep learning pipeline end-to-end to predict each local layered representation for optimal novel view rendering quality using a much smaller neighborhood. Furthermore, we directly pose our algorithm within a plenoptic sampling framework, and our analysis directly applies to the Soft3D algorithm as well. We demonstrate that the high quality of our deep learning predicted local scene representations allows us to synthesize superior renderings without requiring aggregating geometry estimates over large view neighborhoods, as done in Soft3D. This is especially advantageous for rendering non-Lambertian effects because the apparent depth of specularities generally varies with the observation viewpoint, so smoothing the estimated geometry over large viewpoint neighborhoods prevents accurate rendering of non-Lambertian effects.

Other IBR algorithms [Anderson et al. 2016] have attempted to be more robust to incorrect camera poses or scene motion by interpolating views using more general 2D optical flow instead of 1D depth. Local pixel shifts are also encoded in the phase information, and algorithms have exploited this to extrapolate views from micro-baseline stereo pairs [Didyk et al. 2013; Kellnhofer et al. 2017; Zhang et al. 2015] without explicit flow computation. However, these methods require extremely close input views and are not suited for large baseline view interpolation.

2.3 Deep Learning for View Synthesis

Other recent methods have trained deep learning pipelines end-to-end for view synthesis. This includes recent angular superresolution methods [Wu et al. 2017; Yeung et al. 2018] that effectively interpolate dense views within a light field camera baseline, but cannot handle sparser input view sampling since they do not model scene geometry. The DeepStereo algorithm [Flynn et al. 2016] performs unstructured view synthesis by separately predicting a layered scene representation for each novel view. Deep learning based light field camera view interpolation [Kalantari et al. 2016] and single view local light field synthesis [Srinivasan et al. 2017] both predict a depth map for each novel view. However, separately predicting local geometry for each novel view results in inconsistent renderings across smoothly-varying viewpoints.

Finally, Zhou et al. [2018] introduce a deep learning pipeline to predict an MPI from a narrow baseline stereo pair for the task of stereo magnification. As opposed to previous local scene representations used in deep learning, MPIs can render consistent novel views by simple alpha compositing into a target viewpoint. We adopt MPIs as our local light field representation and introduce specific technical improvements to enable larger-baseline view interpolation from many input views using multiple MPIs, as opposed to local view extrapolation from a stereo pair using a single MPI as in [Zhou et al. 2018]. We train our system end-to-end through a blending procedure so the resulting MPIs are optimized to be used together for rendering output views. We propose a 3D CNN architecture that dynamically adjusts the number of depth planes based on the view sampling rate, rather than a 2D CNN with a fixed number of output planes. Additionally, we show that state-of-the-art performance requires only an easily-generated synthetic dataset and a small real fine-tuning dataset, rather than a large real dataset. This allows us to generate training data captured on 2D irregular grids similar to handheld view sampling patterns, while the YouTube dataset in [Zhou et al. 2018] is restricted to 1D camera paths.

3 THEORETICAL SAMPLING ANALYSIS

The overall strategy of our method is to use a deep learning pipeline to promote each sampled view to a layered scene representation with D depth layers, and render novel views by blending between renderings from neighboring scene representations. In this section, we show that the full set of scene representations predicted by our deep network can be interpreted as a specific form of light field sampling. We extend prior work on plenoptic sampling to show...
that our strategy can theoretically reduce the number of required sampled views by up to $D^2 \times$ compared to the number required by traditional Nyquist view sampling. Section 6.1 empirically shows that we are able to take advantage of this bound to reduce the number of required views by up to $64^2 \approx 4000 \times$.

In the following analysis, we consider a “flatland” light field with a single spatial dimension $x$ and view dimension $u$ for notational clarity, but note that all findings apply to general light fields with two spatial and two view dimensions.

### 3.1 Nyquist Rate View Sampling

Initial work on plenoptic sampling [Chai et al. 2000] derived that the Fourier support of a light field, ignoring occlusion and non-Lambertian effects, lies within a double-wedge shape whose bounds are set by the minimum and maximum scene depths $z_{\text{min}}$ and $z_{\text{max}}$, as visualized in Figure 2. Zhang and Chen [2003] showed that occlusions extend the light field’s Fourier support because an occluder convolves the spectrum of the light field due to farther scene content with a kernel that lies on the line corresponding to the occluder’s depth. The light field’s Fourier support considering occlusions is limited by the effect of the closest occluder convolving the line corresponding to the furthest scene content, resulting in the parallelogram shape illustrated in Figure 3a, which can only be packed half as densely as the double-wedge. The required maximum camera sampling interval $\Delta u$ for a light field with occlusions is:

$$\Delta u \leq \frac{1}{2K_x f (1/z_{\text{min}} - 1/z_{\text{max}})}.$$  

(1)

$K_x$ is the highest spatial frequency represented in the sampled light field, determined by the highest spatial frequency in the continuous light field $B_x$ and the camera spatial resolution $\Delta x$:

$$K_x = \min \left( B_x, \frac{1}{2\Delta x} \right).$$  

(2)

### 3.2 MPI Scene Representation and Rendering

The MPI scene representation [Zhou et al. 2018] consists of a set of fronto-parallel RGBzr planes, evenly sampled in disparity within a reference camera’s view frustum (see Figure 4). We can render novel views from an MPI at continuously-valued camera poses within a local neighborhood by alpha compositing the color along rays into the novel view camera using the “over” operator [Porter and Duff 1984]. This rendering procedure is equivalent to reprojecting each MPI plane onto the sensor plane of the novel view camera and alpha compositing the MPI planes from back to front. An MPI can be considered as an encoding of a local light field, similar to layered light field displays [Wetzel et al. 2011, 2012].

### 3.3 View Sampling Rate Reduction

Plenoptic sampling theory [Chai et al. 2000] additionally shows that decomposing a scene into $D$ depth ranges and separately sampling the light field within each range allows the camera sampling interval to be increased by a factor of $D$. This is because the spectrum of the light field emitted by scene content within each range lies within a tighter double-wedge that can be packed $D \times$ more tightly than the full scene’s double-wedge spectrum. Therefore, a tighter reconstruction filter with a different depth can be used for each depth range, as illustrated in Figure 2b. The reconstructed light field, ignoring occlusion effects, is simply the sum of the reconstructions of all layers, as shown in Figure 2c.

Fig. 2. Traditional plenoptic sampling without occlusions, as derived in [Chai et al. 2000]. (a) The Fourier support of a light field without occlusions lies within a double-wedge, shown in blue. Nyquist rate view sampling is set by the double-wedge width, which is determined by the minimum and maximum scene depths $[z_{\text{min}}, z_{\text{max}}]$ and the maximum spatial frequency $K_x$. The ideal reconstruction filter is shown in orange. (b) Splitting the light field into $D$ non-overlapping layers with equal disparity width decreases the Nyquist rate by a factor of $D$. (c) Without occlusions, the full light field spectrum is the sum of the spectra from each layer.

Fig. 3. We extend traditional plenoptic sampling to consider occlusions when reconstructing a continuous light field from MPFs. (a) Considering occlusions expands the Fourier support to a parallelogram (the Fourier support without occlusions is shown in blue and occlusions expand the Fourier support to additionally include the purple region) and doubles the Nyquist view sampling rate. (b) As in the no-occlusions case, separately reconstructing the light field for $D$ layers decreases the Nyquist rate by a factor of $D$. (c) With occlusions, the full light field spectrum cannot be reconstructed by summing the individual layer spectra because the union of their supports is smaller than the support of the full light field spectrum (a). Instead, we compute the full light field by alpha compositing the individual layer light fields from back to front in the primal domain.
However, it is not straightforward to extend this analysis to handle occlusions, because the union of the Fourier spectra for all depth ranges has a smaller support than the original light field with occlusions, as visualized in Figure 3c. Instead, we observe that reconstructing a full scene light field from these depth range light fields while respecting occlusions would be much easier given corresponding per-view opacities, or shield fields [Lanman et al. 2008], for each layer. We could then easily alpha composite the depth range light fields from back to front to compute the full scene light field.

Each alpha compositing step increases the Fourier support by convolving the previously-accumulated light field’s spectrum with the spectrum of the occluding depth layer. As is well known in signal processing, the convolution of two spectra has a Fourier support equal to the sum of the original spectra’s bandwidths. Figure 3b illustrates that the width of the Fourier support parallelogram for each depth range light field, considering occlusions, is:

$$2K_x f \left( \frac{1}{z_{\min}} - \frac{1}{z_{\max}} \right)/D,$$

so the resulting reconstructed light field of the full scene will enjoy the full Fourier support width.

We apply this analysis to our algorithm by interpreting the predicted MPI layers at each camera sampling location as view samples of scene content within non-overlapping depth ranges, and noting that applying the optimal reconstruction filter [Chai et al. 2000] for each depth range is equivalent to reprojecting and then blending pre-multiplied RGBA planes from neighboring MPIs. Our MPI layers differ from layered renderings considered in traditional plenoptic sampling because we predict opacities in addition to color for each layer, which allows us to correctly respect occlusions while compositing the depth layer light fields.

In summary, we extend the layered plenoptic sampling framework to correctly handle occlusions by taking advantage of our predicted opacities, and show that this still allows us to increase the required camera sampling interval by a factor of $D$:

$$\Delta u \leq \frac{D}{2K_x f \left( \frac{1}{z_{\min}} - \frac{1}{z_{\max}} \right)},$$

Our framework further differs from classic layered plenoptic sampling in that each MPI is sampled within a reference camera view frustum with a finite field of view, instead of the infinite field of view assumed in [Chai et al. 2000; Zhang and Chen 2003]. In order for the MPI prediction procedure to succeed, every point within the scene’s bounding volume should fall within the frustums of at least two neighboring sampled views. The required camera sampling interval $\Delta u$ is then additionally bounded by:

$$\Delta u \leq \frac{W \Delta x z_{\min}}{2f},$$

where $W$ is the image width in pixels of each sampled view. The overall camera sampling interval must satisfy both constraints:

$$\Delta u \leq \min \left( \frac{D}{2K_x f \left( \frac{1}{z_{\min}} - \frac{1}{z_{\max}} \right)}, \frac{W \Delta x z_{\min}}{2f} \right).$$

In summary, promoting each view sample to an MPI scene representation with $D$ depth layers allows us to decrease the required view sampling rate by a factor of $D$, up to the required field of view overlap for stereo geometry estimation. Light fields for real 3D scenes must be sampled in two viewing directions, so this benefit is compounded into a sampling reduction of $D^2$. Section 6.1 empirically validates that our algorithm’s performance matches this theoretical analysis. Section 7.1 describes how we apply the above theory along with the empirical performance of our deep learning pipeline to prescribe practical sampling guidelines for users.

### 4 PRACTICAL VIEW SYNTHESIS PIPELINE

We present a practical and robust method for synthesizing new views from a set of input images and their camera poses. Our method first uses a CNN to promote each captured input image to an MPI,
then reconstructs novel views by blending renderings from nearby MPIs. Figure 1 visualizes this pipeline. We discuss the practical image capture process enabled by our method in Section 7.

4.1 MPI Prediction for Local Light Field Expansion

The first step in our pipeline is the expansion of each sampled view to a local light field using an MPI scene representation. We predict an MPI for each input viewpoint using the sampled view along with its four nearest neighbors in 3D space. To predict each MPI from this set of 5 images, we first reproject each image to D depth planes, sampled linearly in disparity within the reference view frustum, to form 5 plane sweep volumes (PSVs) each of size $H \times W \times D \times 3$.

Our MPI prediction CNN takes these 5 PSVs, concatenated along the channel dimension, as input. This CNN outputs an opacity $\alpha$ for each MPI coordinate $(x, y, d)$ as well as a set of 5 color selection weights that sum to 1 at each MPI coordinate. These weights parameterize the RGB values in the output MPI as a weighted combination of the input PSVs. Intuitively, each predicted MPI softly “selects” its color values at each MPI coordinate from the pixel colors at that coordinate in each of the input PSVs. We specifically use this RGB parameterization instead of the foreground-background parameterization proposed by Zhou et al. [2018] because their method does not allow an MPI to directly use content occluded from the reference view but visible in other input views.

Furthermore, we enhance the MPI prediction CNN architecture from the original version to use 3D convolutional layers instead of the original 2D convolutional layers so that our architecture is fully convolutional along the height, width, and depth dimensions. This enables us to predict MPIs with a variable number of planes D so that we can jointly choose the view and disparity sampling densities to satisfy Equation 7. Table 2 validates the benefit of being able to change the number of MPI planes to correctly match our derived sampling requirements, enabled by our use of 3D convolutions. Our full network architecture can be found in Appendix B.

4.2 Continuous View Reconstruction by Blending

As discussed in Section 3, we reconstruct interpolated views as a weighted combination of renderings from multiple nearby MPIs. This effectively combines our local light field approximations into a light field with a near plane spanning the extent of the captured input views and a far plane determined by the field-of-view of the input views. As in standard light field rendering, this allows for a new view path with unconstrained 3D translation and rotation within the range of views made up of rays in the light field.

One important detail in our rendering process is that we consider the accumulated alpha values from each MPI rendering when blending. This allows each MPI rendering to “fill in” content that is occluded from other camera views.

Our MPI prediction network takes in a set of K RGB images $\{C_k\}_{k=1}^K$ along with their camera poses $p_k$ to produce a set of MPIs $M_k$ (one corresponding to each input image). To render a novel view with pose $p_t$ using the predicted MPI $M_k$, we homography warp each RGBxM MPI plane into the frame of reference of the target pose $p_t$ then alpha composite the warped planes together from back to front. This produces an RGB image and an alpha image, which we denote $C_{t,k}$ and $\alpha_{t,k}$ respectively (subscript $t, k$ indicating that we rendered the output image at pose $p_t$ using the MPI residing at pose $p_k$).

Since a single MPI alone will not necessarily contain all the content necessary to render the new view, owing to occlusions and field of view issues, we render the final RGB output $C_t$ by blending the rendered RGB images $C_{t,k}$ from multiple MPIs. We use blending weights $w_k$, each modulated by the corresponding accumulated alpha images $\alpha_{t,k}$ and normalized so that the resulting rendered image is fully opaque ($\alpha = 1$):

$$C_t = \frac{\sum_k w_k \alpha_{t,k} C_{t,k}}{\sum_k w_k \alpha_{t,k}}.$$  \hspace{1cm} (8)

For an example where modulating the blending weights by the accumulated alpha values prevents artifacts, see Figure 6. Table 2 demonstrates that blending with alpha gives quantitatively superior results over both using a single MPI and blending multiple MPIs without alpha.

The blending weights $w_k$ can be any sufficiently smooth filter. In the case of data sampled on a regular grid, we use bilinear interpolation from the four nearest MPIs rather than the ideal sinc function interpolation for efficiency and due to the limited number of sampled views. For irregularly sampled data, we use the five nearest MPIs and take $w_k \propto \exp(-y d_k)$, where $d_k$ is the $L^2$ distance to the novel view and $y = \int_{Dz_0}^f$ for focal length $f$, minimum distance to the scene $z_0$, and number of planes $D$. (Note that the quantity $\frac{d_k}{z_0}$ represents $d_k$ converted into units of pixel disparity.)

Our strategy of blending between neighboring MPIs is particularly effective for rendering non-Lambertian effects. For general
We train our view synthesis pipeline using both renderings and real data with texture-mapped surfaces and low geometric complexity. Using real data helps us generalize to real-world lighting and reflectance effects as well as small errors in pose estimation. Our real training dataset consists of 24 scenes from our handheld cellphone captures, with 20-30 images each. We use the COLMAP structure from motion [Schönberger and Frahm 2016] implementation to compute poses for our real images. For each training step, we sample two sets of 5 views each to use as inputs, and a single held-out target view for supervision.

5.2 Training Procedure

We first use the MPI prediction network to separately predict an MPI for each set of 5 inputs. Next, we render the target novel view from each MPI and blend these renderings using the accumulated alpha values, as described in Equation 8. The training loss is simply the image reconstruction loss for the rendered novel view. We follow the original work for MPI prediction [Zhou et al. 2018] and use the VGG network activation perceptual loss as implemented by Chen and Koltun [2017], which has been consistently shown to outperform standard image reconstruction losses [Huang et al. 2018; Zhang et al. 2018]. We are able to train on the final blended rendering because our fixed rendering and blending functions are differentiable. Learning through this fixed blending step trains our MPI prediction network to leave alpha “holes” in uncertain regions for each MPI, in the expectation that this content will be better rendered by another neighboring MPI, as illustrated by Figure 6.

In practice, training through blending is slower than training a single MPI, so we first train on rendering a new view from one MPI for 500k iterations, then fine tune through two views blended from different MPIs for 100k iterations. When running the final network on real data, we fine tune on our real dataset for an additional 10k iterations. We use 320 × 240 resolution and up to 128 planes for SUNCG training data, and 640 × 480 resolution and up to 32 planes for UnrealCV training data, due to GPU memory limitations. We implement our full pipeline in Tensorflow [Abadi et al. 2015] and optimize the MPI prediction network parameters using Adam [Kingma and Ba 2015] with a learning rate of 2 × 10⁻⁴ and a batch size of one. We split the training pipeline across two Nvidia RTX 2080 Ti GPUs, and use a single GPU for each of the two MPIs whose renderings are then blended before computing the training loss.

6 EXPERIMENTAL EVALUATION

We quantitatively and qualitatively validate our method’s prescriptive sampling benefits and ability to render high fidelity novel views of light fields that have been undersampled by up to 4000×, as well as demonstrate that our algorithm outperforms state of the art methods for regular view interpolation. Figure 9 showcases these qualitative comparisons on scenes with complex geometry (Fern and T-Rex) and highly non-Lambertian scenes (Air Plants and Pond) that are not handled well by most view synthesis algorithms.

For all quantitative comparisons (Table 2), we use a synthetic test set rendered from an UnrealCV [Qiu et al. 2017] environment that was not used to generate any training data. Our test set contains 8 scenes, each rendered at 640 × 480 resolution and at 8 different view positions.
Fig. 8. We plot the performance of our method (with varying number of planes \( D = 8, 16, 32, 64, \) and 128) compared to light field interpolation for different input view sampling rates (denoted by maximum scene disparity \( d_{\text{max}} \) between adjacent input views). Our method can achieve the same perceptual quality as LFI with Nyquist rate sampling (black dotted line) as long as the number of predicted planes matches or exceeds the undersampling rate, up to an undersampling rate of 128. At \( D = 64 \), this means we achieve the same quality as LFI with \( 64^2 = 4000 \times \) fewer views. We use the LPIPS [Zhang et al. 2018] metric (lower is better) because we specifically care about perceptual quality. The colored dots indicate the point on each line where the number of planes equals the disparity range, where equality is achieved in our sampling bound (Equation 7). The shaded region indicates \( \pm 1 \) standard deviation over all 8 test scenes.

6.1 Sampling Theory Validation
Our method is able to render high-quality novel views while significantly decreasing the required input view sampling density. The graph in Figure 8 shows that our method is able to render novel views with Nyquist level perceptual quality up to and including \( D = 64 \) pixels of disparity between input view samples, as long as we match the number of planes in each MPI to the maximum pixel disparity between input views. We postulate that our inability to match Nyquist quality from input images with a maximum of 128 pixels of disparity is due to the following factors:

1. As the maximum disparity between adjacent views increases, any non-foreground scene point is likely sampled by fewer input views, which makes it harder for the CNN to find matches in the plane sweep volume and correctly estimate its depth.
2. At our test resolution of \( 640 \times 480 \) and 128 pixels of disparity, the field of view overlap between neighboring images is close to the limit of our inequality in Equation 5.

Figure 8 also shows that once our sampling bound is satisfied, adding additional planes does not increase performance. For example, at 32 pixels of disparity, increasing from 8 to 16 to 32 planes decreases the LPIPS error, but performance stays constant from 32 to 128 planes. This verifies that for scenes up to 64 pixels of disparity, adding additional planes past the maximum pixel disparity between input views is of limited value, in accordance with our theoretical claim that partitioning a scene with disparity variation of \( D \) pixels into \( D \) depth ranges is sufficient for continuous reconstruction.

6.2 Comparisons to Baseline Methods
We quantitatively (Table 2) and qualitatively (Figure 9) demonstrate that our algorithm produces superior renderings, particularly for non-Lambertian effects, without the artifacts seen in renderings from competing methods. We urge readers to view our accompanying video for convincing rendered camera paths that highlight the benefits of our approach compared to competing methods.

We use the synthetic test set described above to compare our method to state-of-the-art view synthesis techniques as well as view-dependent texture-mapping using a global mesh proxy geometry. Please refer to Appendix A for additional implementation details regarding baseline methods.

Soft3D [Penner and Zhang 2017]. Soft3D is a state-of-the-art view synthesis algorithm that is similar to our approach in that it also computes a local layered scene representation for each input view and projects and blends these volumes to render each novel view. However, it uses a hand-crafted pipeline based on classic local stereo and guided filtering to compute each layered representation. Furthermore, since classic stereo methods are unreliable for smooth or repetitive image textures and non-Lambertian materials, Soft3D relies on smoothing their geometry estimation across many (up to 25) input views.

Table 2 quantitatively demonstrates that our approach outperforms Soft3D overall. In particular, Soft3D’s performance degrades much more rapidly as the input view sampling rate decreases since their aggregation is less effective as fewer input images view the same scene content. Our method is able to maintain high-quality performance and predict “complete” and “smooth” geometry in scenarios where Soft3D suffers from noisy and erroneous results of local stereo because we leverage deep learning to learn implicit priors on natural world geometry. This is in line with recent work that has shown the benefits of deep learning over traditional stereo for depth estimation [Huang et al. 2018; Kendall et al. 2017].

Figure 9 qualitatively demonstrates that Soft3D generally contains blurred geometry artifacts due to errors in local depth estimation, and that Soft3D’s approach fails for rendering non-Lambertian
We use a plane at the mean scene disparity as a proxy geometry to fill in holes in the mesh. It is particularly difficult to reconstruct a global mesh with geometry edges that are well-aligned with image edges, which causes perceptually jarring artifacts. Furthermore, mesh reconstruction often fails to fill in large portions of the scene, resulting in ghosting artifacts similar to those seen in light field interpolation.

**Backwards warping deep network (BW Deep).** This baseline subsumes recent deep learning view synthesis techniques [Flynn et al. 2016; Kalantari et al. 2016], which use a CNN to estimate geometry for each novel view and then backwards warp and blend nearby input images to render the target view. We train a network that uses the same 3D CNN architecture as our MPI prediction network but instead outputs a single depth map at the pose of the new target view. We then backwards warp the five input images into the new view using this depth map and use a second 2D CNN to composite these warped input images into a single output rendered view.

As shown in Table 2, performance for this method degrades quickly as the maximum disparity increases. Although this approach produces comparable images for scenes with small disparities (\(d_{\text{max}} = 16, 32\)), the renderings suffer from extreme inconsistency when rendering video sequences.

BW Deep methods use a CNN to estimate depth separately for each output viewpoint, so artifacts appear and disappear over only a few frames, resulting in rapid flickers and pops in the rendered camera path. This inconsistency is visible as corruption in the epipolar plots in Figure 9 and can be clearly seen in our supplemental video. Furthermore, backwards warping incentivizes incorrect depth predictions to fill in disocclusions, so BW Deep methods also contain errors around thin structures and occlusion edges.

**Unstructured Lumigraph Rendering (ULR) [Buehler et al. 2001].** This baseline is representative of classic signal processing based continuous view reconstruction. Following the method of plenoptic sampling [Chai et al. 2000], we render novel views using a bilinear interpolation reconstruction filter sheared to the mean scene disparity. Figure 9 demonstrates that increasing the camera spacing beyond the Nyquist rate results in extreme aliasing and ghosting artifacts when using this method.

### 6.3 Ablation Studies

We validate our overall strategy of blending between multiple MPIs as well as our specific blending procedure that considers accumulated alphas through the following ablation studies:

**Single MPI.** The fifth row of Table 2 shows that using only one MPI to produce new views results in significantly decreased performance due to the limited field of view represented in a single MPI as well as depth discretization artifacts as the target view moves far from the MPI reference viewpoint. Additionally, Figure 7 shows an example of complex non-Lambertian reflectance that cannot be represented by a single MPI. This can be considered an upper bound on the performance of [Zhou et al. 2018], since we use only one MPI but generate it with a higher capacity 3D CNN.

**Average MPIs.** The sixth row of Table 2 shows that blending multiple MPI outputs for each novel view without using the accumulated alpha channels results in decreased performance. Figure 6 visualizes that this simple blending leads to ghosting in regions that are occluded from the inputs of any of the MPIs used for rendering, because they will contain incorrect content in disoccluded regions.

### 7 PRACTICAL USAGE

We present sampling guidelines to assist users in sampling views that enable high-quality view interpolation with our algorithm, and showcase our method’s practicality with a smartphone camera app that guides users to easily capture such input images. Furthermore, we implement a fast mobile viewer that renders novel views from our predicted MPIs in real-time. Figure 9 showcases example rendered images because their aggregation procedure blurs the specularity geometry, which changes with the input image viewpoint.
Fig. 9. Results on real cellphone datasets. We render a sequence of new views and show both a crop from a single rendered output and an epipolar slice of the sequence. We show 2D projections of the input camera poses (blue dots) and new view path (red line) along the $z$ and $y$ axes of the new view camera in the lower left of each row. LFI fails to cleanly represent objects at different depths because it only uses a single depth plane for reprojection, leading to ghosting (leaves in Fern, lily pads in Pond) and depth inconsistency visible in all epipolar images. Mesh reconstruction failures cause artifacts visible in both the crops and epipolar images for ULR. Soft3D’s depth uncertainty leads to blur, and geometry aggregation across large view neighborhoods results in incorrect specularity geometry (brown and blue reflections in Pond). BW Deep’s use of a CNN to render every novel view causes depth inconsistency, visible as choppiness across the rows of the epipolar images in all examples. Additionally, BW Deep selects a single depth per pixel, leading to errors for transparencies (glass rim in Air Plants) and reflections (Pond). BW Deep also uses backwards warping, which causes errors around occlusion boundaries (thin ribs in T-Rex). We urge the reader to refer to our supplemental video for high quality videos of these rendered camera paths and additional discussion.
results from handheld smartphone captures. Our accompanying video contains a screen capture of our app in use, as well as results on over 50 real-world scenes generated by an automated script.

7.1 Prescriptive Scene Sampling Guidelines
In a typical capture scenario, a user will have a camera with a field of view $\theta$ and a view plane with side length $S$ that bounds the viewpoints they wish to render. Based on this, we prescribe the design space of image resolution $W$ and number of images to sample $N$ that users can select from to reliably render novel views at Nyquist level perceptual quality.

Section 6.1 shows that the empirical limit on the maximum disparity $d_{\text{max}}$ between adjacent input views for our deep learning pipeline is 64 pixels. Substituting Equation 7:

$$\frac{\Delta u f}{\Delta x z_{\text{min}}} \leq 64$$

(9)

We translate this into user-friendly quantities by noting that $\Delta u = S/\sqrt{N}$ and that the ratio of sensor width to focal length $W\Delta x/f = 2\tan(\theta/2)$:

$$\frac{W}{\sqrt{N}} \leq \frac{128z_{\text{min}} \tan(\theta/2)}{S}$$

(10)

Using a smartphone camera with a 64° field of view, this is simply:

$$\frac{W}{\sqrt{N}} \leq \frac{80z_{\text{min}}}{S}$$

(11)

Intuitively, once a user has determined the extent of viewpoints they wish to render and the depth of the closest scene point, they can choose any target rendering resolution $W$ and number of images to capture $N$ such that the ratio $W/\sqrt{N}$ satisfies the above expression.

7.2 Asymptotic Rendering Time and Space Complexity
Within the possible choices of rendering resolution $W$ and number of sampled views $N$ that satisfy the above guideline, different users may value the capture time, rendering time, and storage costs differently. We derive the asymptotic complexities of these quantities to further assist users in choosing correct parameters for their application.

First, the capture time is simply $O(N)$. The render time of each MPI generated is proportional to the number of planes times the pixels per plane:

$$W^2D = \frac{W^3S}{2\sqrt{N}z_{\text{min}} \tan(\theta/2)} = O(W^3N^{-1/2}).$$

(12)

Note that the rendering time for each MPI decreases as the number of sampled images $N$ increases, because this allows us to use fewer planes per MPI. The total MPI storage cost is proportional to:

$$W^2D \cdot N = \frac{W^3S\sqrt{N}}{2z_{\text{min}} \tan(\theta/2)} = O(W^3\sqrt{N}).$$

(13)

Practically, this means that users should determine their specific rendering time and storage constraints, and then maximize the image resolution and number of sampled views that satisfy their constraints as well as the guideline in Equation 10. Figure 10 visualizes these constraints for an example user.

7.3 Smartphone Capture App
We develop an app for iOS smartphones, based on the ARKit framework, that guides users to capture input views for our view synthesis algorithm. The user first taps the screen to mark the closest object, and the app uses the corresponding scene depth computed by ARKit as $z_{\text{min}}$. Next, the user selects the size of the view plane $S$ within which our algorithm will render novel views. We fix the rendering resolution for the smartphone app to $W = 500$ which therefore fixes the prescribed number and spacing of required images based on Equation 11 and the definition $\Delta u = S/\sqrt{N}$. Our app then guides the user to capture these views using the intuitive augmented reality overlay visualized in Figure 11. When the phone detects that the camera has been moved to a new sample location, it automatically records an image and highlights the next sampling point.
7.4 Preprocessing
After capturing the required input images, the only preprocessing required before being able to render novel views is estimating the input camera poses and using our trained network to predict an MPI for each input view. Unfortunately, camera poses from ARKit are currently not accurate enough for acceptable results, so we use the open source COLMAP software package [Schönbberger and Frahm 2016; Schönberger et al. 2016], which takes about 2-6 minutes for sets of 20-30 input images.

We use the deep learning pipeline described in Section 4.1 to predict an MPI for each input sampled view. On an Nvidia GTX 1080Ti GPU, this takes approximately 0.5 seconds for a small MPI (500 × 350 × 32 ≈ 6 megavoxels) or 12 seconds for a larger MPI that must be produced in patches (1000 × 700 × 64 ≈ 45 megavoxels). In total, our method only needs about 10 minutes of preprocessing to estimate poses and predict MPFs before being able to render novel views at a 1 megapixel image resolution.

With the increasing investment in smartphone AR and on-device deep learning accelerators, we expect that smartphone pose estimation will soon be accurate enough and on-device network inference will be powerful enough for users to go from capturing images to rendering novel views within a few seconds.

7.5 Real-Time Viewers
We implement rendering novel views from a single MPI as rasterizing each plane from back to front as texture-mapped rectangles in 3D space, and using a standard shader API to correctly handle the alpha compositing, perspective projection, and texture resampling. For each new view, we determine the MPFs to be blended, as discussed in Section 4.2, and render them into separate framebuffers. We then use a simple fragment shader to perform the alpha-weighted blending described in Section 4.2. We implement this rendering pipeline as a desktop viewer using OpenGL which renders views with 1000 × 700 resolution at 60 frames per second, as well as an iOS mobile viewer using the Metal API which renders views with 500 × 350 resolution at 30 frames per second. Please view our included video for demonstrations of these real-time rendering implementations.

7.6 Limitations
A main limitation of our algorithm is that our MPI network sometimes assigns high opacity to incorrect layers in regions of ambiguous or repetitive texture and regions where the scene moves between input images. This can cause floating or blurred patches in the rendered output sequence (see the far right side of the fern in our video), which is a common failure mode in methods that rely on texture matching cues to infer depth. These artifacts could potentially be ameliorated by using more input views to disambiguate stereo matching and by encouraging the network to learn stronger global priors on 3D geometry.

Another limitation is the difficulty of scaling to higher image resolutions. As evident in Equations 12 and 13, layered approaches such as our method are limited by complexities that scale cubically with the image width in pixels. Furthermore, increasing the image resolution requires a CNN with a larger receptive field. This could be addressed by exploring multiresolution CNN architectures and hierarchical volume representations such as octrees, or by predicting a more compact local scene representation such as layered depth images [Shade et al. 1998] with opacity.

8 CONCLUSION
We have presented a simple and practical method for view synthesis that works reliably for complex real-world scenes, including non-Lambertian materials. Our algorithm first promotes each input image into a layered local light field representation, then renders novel views in real time by blending outputs generated by nearby representations. We extend traditional plenoptic sampling analysis to handle occlusions, and provide a theoretical sampling bound on how many views are needed for our method to render high-fidelity views of a given scene. We quantitatively validate this bound and demonstrate that we match the perceptual quality of dense Nyquist rate view sampling while using ≈ 4000× fewer input images. Our accompanying video demonstrates that we thoroughly outperform prior work, and showcases results on over 60 diverse and complex real-world scenes, where our novel views are rendered with a fully automated capture-to-render pipeline. We believe that our work paves the way for future advances in image-based rendering that combine the performance benefits of empirical data-driven machine learning methods with the robust reliability guarantees of traditional geometry and signal processing analysis.

A BASELINE METHODS IMPLEMENTATION DETAILS
Here we provide additional implementation details regarding the baseline comparison methods described in Section 6.2.

Soft3D [Penner and Zhang 2017]. We implemented this algorithm from the description provided in the original paper, since no open-source implementation is currently available. We provide Soft3D’s local stereo stage with the same 5 input images used to compute each of our MPFs, for fair comparison. Next, we aggregate Soft3D’s computed vote volumes across 25 viewpoints, as suggested in their paper for 2D view captures. Finally, we compute each rendered novel view using the Soft3D volumes corresponding to the same 5 viewpoints whose MPFs we use for our algorithm. The guided filter parameters are not specified in the original Soft3D paper, but we find that best results were obtained using a window size of 8 and ε = 20 for images with values in the range (0,255). Please refer to our supplemental video to see results of our Soft3D implementation on a scene shown in the original paper’s video to verify that our implementation is of similar quality.
Table 3. Our network architecture. \(k\) is the kernel size, \(s\) the stride, \(d\) the kernel dilation, \(chns\) the number of input and output channels for each layer, \(in\) and \(out\) are the accumulated stride for the input and output of each layer, \(input\) denotes the input of each layer with + meaning concatenation, and layers starting with “\(nnup\)” perform \(2 \times \) nearest neighbor upsampling.
